Dual Solutions for Opposing Mixed Convection in Porous Media

The problem of steady mixed convection boundary layer flow on a cooled vertical permeable circular cylinder embedded in a fluid-saturated porous medium is studied. Here, we evaluate the flow and heat transfer characteristics numerically for various values of the governing parameters and demonstrate the existence of dual solutions beyond a critical point. [DOI: 10.1115/1.4036727]

Keywords: mixed convection, porous medium, vertical permeable circular cylinder, dual solutions

1 Introduction

Convective heat transfer in fluid-saturated porous media has received a great amount of attention during the last few decades. This has been driven by its importance in many aspects of natural and industrial problems, such as the utilization of geothermal energy, chemical engineering, food processing and storage, nuclear waste management, thermal insulation system, contaminant transport in ground water, migration of moisture through air contained in fibrous insulation, and many others. Several reviews of the subject of convective flow in porous media were done by various researchers [1–6].

Mixed convection from a vertical cylinder embedded in a porous medium is the principal mode of heat transfer in numerous applications such as in connection with oil/gas lines, insulation of vertical porous pipes, cryogenics as well as in the context of water distribution lines, underground electrical power transmission lines, and disposal of radioactive waste, to name just a few applications. The case of free and mixed convection flow from a vertical cylinder placed in a porous medium has been studied extensively both analytically and numerically. A numerical solution of the problem of free convective boundary layer flow induced by a heated vertical cylinder embedded in a fluid-saturated porous medium was presented by Minkowycz and Cheng [7] when the surface temperature of the cylinder was taken to be proportional to \( x^n \) where \( x \) was the distance from the leading edge of cylinder and \( n \) was a constant. The results were obtained for various values of \( n \) lying between 0 and 1, by using similarity and local nonsimilarity methods [8–14]. The problem was later extended by various researchers [15–22]. Bassom and Rees [19] studied the free convection boundary layer flow induced by a heated vertical cylinder embedded in a fluid-saturated porous medium, with the surface temperature of the cylinder varying as \( x^n \). Both numerical and asymptotic analyses were presented for the governing nonsimilar boundary layer equations. When \( n \leq 1 \), the asymptotic flow field far from the leading edge of cylinder was taken on a multiple-layer structure. On the other hand, for \( n > 1 \), only a single layer was present far downstream, but a multiple layer structure existed close to the leading edge of the cylinder.

In this paper, we consider the problem of mixed convection boundary layer flow along a cooled vertical permeable circular cylinder embedded in a fluid-saturated porous medium, shown in Fig. 1. It is assumed that the mainstream velocity \( U(x) \) and surface temperature \( T_w(x) \) of the cylinder vary linearly with the distance \( x \) along the cylinder. It is also assumed that the axially symmetric surface mass flux \( \omega \) is constant. The similarity equation involves three parameters, namely, the buoyancy convection parameter \( \lambda \), curvature parameter \( \gamma \), and suction or blowing parameter \( \sigma \). It should be stated at this end that mixed convection flows, or the combination of both free and forced convection, occur in many transport processes in natural and industrial applications, including electronic device cooled by a fan, nuclear reactor during emergency shutdown, heat exchange in low-velocity environment, and solar receiver exposed to wind current. The effect of buoyancy induced flow in forced convection or forced flow in free convection becomes significant for such transport processes. When the flow velocity is relatively low and the temperature difference

---

Fig. 1 Physical model and coordinate system
between the surface and the free stream is relatively large, thermal buoyancy forces play a significant role in forced convection heat transfer as well as in the onset of flow instabilities, because of being responsible for delaying or speeding up the transition from laminar to turbulent flow (see Ref. [23]). These authors have shown that the mixed convection regime is \( \alpha \leq G_r/R_e^\gamma \leq b \), where \( G_r \) is the Grashof number, \( R_e \) is the Reynolds number, \( n \) is a constant, which depends on flow configuration and surface heating condition, and \( a \) and \( b \) are the lower and upper bounds of regime, respectively. The buoyancy parameter \( G_r/R_e^\gamma \) represents a measure of the effect of free convection in comparison to that of forced convection on the flow. Outside the mixed convection regime, the analysis of a pure either free or forced convection can be adopted to describe the flow and temperature field accurately.

2 Governing Equations

For the Darcy steady mixed convection flow of a viscous incompressible fluid along the vertical permeable circular cylinder of radius \( r_0 \) embedded in a fluid-saturated porous medium with prescribed axially symmetric velocity \( v_w \), wall temperature \( T_w(x) \) and mainstream velocity \( U(x) \) in fluid at constant ambient temperature \( T_\infty \), the governing equations for continuity, Darcy with Boussinesq approximation, and energy can be written by using the usual boundary layer approximation as (see Refs. [5] and [17] or [19])

\[
\frac{\partial (ru)}{\partial x} + \frac{\partial (rv)}{\partial r} = 0 \tag{1}
\]

\[
u = U(x) + \frac{g \beta K}{\nu} (T - T_\infty) \tag{2}
\]

subject to the boundary conditions

\[ v = v_w, \quad T = T_w(x) \text{ at } r = r_0 \tag{4} \]

\[ u = U(x), \quad T \rightarrow T_\infty \text{ as } r \rightarrow \infty \tag{5} \]

Here, the coordinates \( x \) and \( r \) measure distance along the surface and normal to it, respectively; \( u \) and \( v \) are the velocity components along \( x \) and \( r \) axes; \( T \) is the fluid temperature; \( g \) is the acceleration due to gravity; \( K \) is the permeability of the porous medium; \( \nu \) is the kinematic viscosity; \( \alpha \) is the effective thermal diffusivity; and \( v_w \) is the velocity of suction \((v_w < 0)\) or blowing \((v_w > 0)\), respectively. Following Mahmood and Merkin [18], we assume in this paper that

\[
U(x) = \frac{U_\infty x}{L} \quad \text{and} \quad T_w(x) = T_\infty + \frac{x \Delta T}{L} \tag{6}
\]

where \( \Delta T \) and \( L \) are the temperature and length characteristics. With this choice of mainstream and cylinder temperature, Eqs. (1)–(3) can be reduced to similarity form by introducing the variables

\[
\psi = \frac{2 \alpha}{\gamma} f(\eta), \quad T = T_\infty + \frac{x \Delta T}{L} \theta(\eta), \quad \eta = \frac{r^2 - r_0^2}{r_0^2} \tag{7}
\]

where \( \gamma = (2/r_0) \sqrt{\alpha L/U_\infty} \) is the curvature parameter and \( \psi \) is the stream function defined in the usual way

\[
u = -\frac{1}{r} \frac{\partial \psi}{\partial x} \tag{8}
\]

Equations (1)–(3) then become

\[
f'' = 1 + \lambda \theta \tag{9}
\]

\[
(1 + \gamma \eta) \theta'' + \gamma \theta' + f' \theta' - f' \theta = 0 \tag{10}
\]

with the boundary conditions

\[
f(0) = \sigma, \quad \theta(0) = 1, \quad \theta(\infty) = 0 \tag{11}
\]

Here, \( \lambda = Ra/Pe \) is the buoyancy parameter (ratio of free to forced convection velocity scales). \( Ra = g \beta K \Delta T/\alpha \nu \) is the Rayleigh number, \( Pe = U_\infty L/\alpha \) is the Péclet number, and \( \sigma = -v_w \alpha (2/r_0) / \alpha \) is the suction \((\sigma > 0)\) or blowing \((\sigma < 0)\) parameter. Primes denote differentiation with respect to \( \eta \). Combining Eqs. (9) and (10), we finally have the equation

\[
(1 + \gamma \eta) f''' + f'' + \gamma f'' + f' - f'^2 = 0 \tag{12}
\]

along with the boundary condition

\[
f(0) = \sigma, \quad f'(0) = 1 + \lambda, \quad f'(\infty) = 1 \tag{13}
\]

The physical quantity of interest is the skin friction coefficient \( C_f \), which is defined as

\[
C_f = \frac{1}{\tau_w} \frac{\tau_w}{\frac{1}{2} \rho U_\infty^2} \tag{14}
\]

where the skin friction \( \tau_w \) is given by

\[
\tau_w = \frac{1}{2} \rho \left. \frac{\partial u}{\partial r} \right|_{r=r_0} \tag{15}
\]

Using the similarity variables (7), we have the reduced skin friction

\[
f''(0) = C_f \frac{\alpha}{2 \nu} \tag{16}
\]

3 Results and Discussion

Equation (12) with the boundary conditions (13) has been solved numerically for the selected values of the governing parameters by using the standard numerical method [24]. Our principal objectives being to assess the effects that mixed convection, curvature, and suction parameters have on the flow and heat transfer characteristics. It is worth pointing out that some special cases have been considered for \( \gamma/(2 + \lambda + \sigma) = 1 \) [25], \( \gamma = 0 \), \( \sigma = 0 \) [26], and \( \sigma = 0 \) [27]. All values of three parameters, the buoyancy convection parameter \( \lambda \), curvature parameter \( \gamma \), and suction or blowing parameter \( \sigma \), are presented as follows.

In Figs. 2–4, the reduced skin friction \( f''(0) \) is plotted against the mixed convection parameter \( \lambda \) for various values of the
The full Darcy and energy equations should be solved for obtaining due to boundary layer separation from the surface. The boundary layer solutions beyond this point are impossible to be obtained due to boundary layer separation from the surface. The full Darcy and energy equations should be solved for \( \lambda_c \leq \lambda < 0 \), where \( \lambda_c < 0 \) is the critical value of \( \lambda < 0 \), and all values of \( \gamma \) and \( \sigma \) considered.

The two branches (upper and lower branch solutions) merge with one another at a critical point \( k_c < 0 \). A stability analysis by adopting the techniques of Merkin [16] and Wilks and Bramley [28] reveals that the upper branch solutions are stable and physically realizable, while the lower branch solutions are unstable and, therefore, not physically realizable. It is to be noticed that the problem (12) and (13) admits an exact solution for the special case \( \gamma r_0/C_0/C_1 = 0 \) (see Ref. [25]).

\[
f(\eta) = \sigma + \eta + \lambda_c (1 - e^{-\gamma})
\]  

(17)

It should be stated that the results obtained by Magyari et al. [25] are, in fact, identical with the numerical results obtained from Eq. (12) subject to Eq. (13) in this paper. We found, however, that our numerical results are quantitatively consistent with the analytical results reported by Magyari et al. [25]. Thus, it gives us confidence that the present numerical results are correct for all values of \( \lambda, \gamma, \) and \( \sigma \) considered.

Finally, we also include the plots of the velocity profile \( f'(\eta) \) in Fig. 5, which shows the existence of dual solutions of the problem (12) and (13). It is clearly seen from these figures that boundary layer thickness becomes thinner for the upper branch solution as compared to the lower branch solution and the far-field boundary conditions (13) are satisfied asymptotically. Therefore, it confirms the validity of the numerical results and the existence of the dual solutions illustrated in Figs. 2 and 4.

4 Conclusion

In summary, the problem of steady mixed convection boundary layer flow on a cooled vertical permeable circular cylinder embedded in a fluid-saturated porous medium is studied. We take particular forms for the outer flow and wall temperature variation that enable the system of the partial differential equations to be reduced to a similarity form. Eqs. (12) and (13). For an opposing flow (\( \lambda < 0 \)), we find that there is a critical value \( \lambda_c < 0 \) of the mixed convection parameter \( \lambda < 0 \), with solutions existing only for \( \lambda_c \leq \lambda < 0 \). However, for \( \lambda < \lambda_c < 0 \), the solutions of the problem (12) and (13) do not exist. We then examined the effects of the curvature \( \gamma \) and mass flux \( \sigma \) parameters on the reduced skin friction \( f''(0) \) and velocity profile \( f'(\eta) \). Graphical qualitative
comparison has been made with the existing results in literature and it is found to be in good agreement. It is worth mentioning at this end that Wilks and Bramley [28] presented dual similarity solutions in the context of mixed convection flow. They showed that for this flow, dual solution existed and they displayed reverse flow. In contrast to the Falkner–Skan solutions, the bifurcation point was to be distinct from the point of vanishing skin friction.

A significant feature of the new solutions discovered by Wilks and Bramley [28] was the location of the bifurcation point, separating two branches of solution, away from the point of vanishing skin friction.
